1 Life table

In this practical, you will work with life tables. Read the following text carefully and do the exercise at the end of this section. The first part is the description of a hypothetical barn owl population and the second part is brief reminder of life table theory.

Figure 1: Barn owl, from wikipedia.

1.1 A barn owl population

The barn owl (Schleiereule in German) is a common nocturnal prey bird (see fig. 1). We focus on a cohort of female barn owls that were born in 2010 and who have all died by the beginning of 2014.

- In 2010, 10 female chicks were born and were followed over the years.
- In 2011, 8 of them were still alive. Only 4 females of this cohort reproduced in 2011: two produced 4 female chicks, one produced 3 female chicks and the last one produced 5 female chicks.
- In 2012 only 4 females were still alive. This time, they each produce 3 female chicks.
- In 2013, only one individual of the original cohort was still alive and had only one female chick.
- In 2014, all individuals were dead.

1.2 Standard cohort life table

Table 1 contains the standard life-table calculation. Below is a description of each column. We purposefully do not provide you with the equations to obtain each value, we left this for you to find out.

- *The first column x* is the age of the individuals. By convention, the new-born start at age 0 and are age 1 at their first birthday.

Table 1: An example of a life table.

x	$S(x)$	$b(x)$	$l(x)$	$g(x)$	Rep. rate
0	10
1	8
2
3
4

- The second column $S(x)$ is the number of individuals of the cohort still alive at age x .
- The third column $b(x)$ is the fecundity schedule (sometimes it is referred to as $m(x)$, m for maternity). It is the **average number of female offspring born per unit of time to a female of a given age**.
- The fourth column $l(x)$ is the survivorship schedule, not to be confused with the survival probability $g(x)$. It is defined as the **proportion of the original cohort that survives to a given age**. Or in other words it is the probability that an individual survives from birth to age x .
- The fifth column $g(x)$ is the survival probability. It is different from the survivorship schedule in that it is the **probability that an individual of age x survives to age $x + 1$** .
- The sixth column Rep. rate is what we call the reproductive rate: what is the mean number of offspring that each individual produce at a given age, regardless of whether the individual survives until that age. We are in fact interested in the **net reproductive rate**, R_0 but to find it, we must first find the reproductive rate of each age. The net reproductive rate is defined as the **mean number of female offspring produced per female individual over their lifetime**. It is the reproductive potential of a female corrected for its mortality.

In addition to the elements of the table, there are a few more important properties you can extract from the life table. A general property of the table is, G , the generation time. A definition of the generation time is **the average age of mothers when they give birth**. From the life table, you can also calculate the instantaneous rate of increase, r . Remember from Arpat's lecture on unstructured population that:

$$N_t = N_0 e^{rt} \quad (1)$$

The exact solution of r is given by solving the following equation adapted from the Lotka-Euler equation for r :

$$1 = \sum_{x=0}^k e^{-rx} l(x) b(x) \quad (2)$$

This equation can only be solved iteratively. Alternatively, an approximation of r is given by:

$$r \approx \frac{\ln(R_0)}{G} \quad (3)$$

* Exercise 1 Life Table

Write on paper a life table for the hypothetical barn owl population described above. Your life table should be organised like table 1 and contain the same columns. For each column, write the corresponding equation.

In addition, find R_0 , G and the approximation of r .

2 Age-structured Matrix Analysis

In the former section, we have followed the fate of a hypothetical cohort of barn owls. Let us now look at the transition matrix. We want to know the number of individuals in each age class. Imagine these 10 female barn owls are the founders of a new population and we do a postbreeding census, in which females are counted each year just after they have bred.

- In 2010, there are 10 females in age class 1.
- In 2011 there are 8 females in age class 2 and 16 females in age class 1.
- In 2012 there are 4 females in age class 3, 13 females in age class 2 and 12 females produced by the individuals in age class 2 and 26 females produced by the females in age class 1.
- In 2013 there is 1 female in age class 4, 7 in age class 3 and 30 in age class 2. There are in addition 81 new individuals in age class 1: 1 from the females in age class 3, 19 from the females in age class 2 and 61 from the females in age class 1. The survival rate of the age class 4 is 0.

* Exercise 2 Age-structured matrix

1. Let us work out the matrix of this barn owl population on paper.
 - a) First, draw the life cycle of the population of barn owls describe above.
 - b) Find the survival probability P_i for each age class i , that is the probability of an individual in age class i to age class $i + 1$.
 - c) Find the fertility F_i , the average number of offspring produced by an individual of age class i .
 - d) Write the equations to get the number of individuals in each age class at time $t + 1$. Your equations should be of the form $n_1(t + 1) = F_1 n_1(t)$.
 - e) What is the structure of the corresponding Leslie matrix? What is the dimension of your matrix?
 - f) Build the corresponding Leslie matrix of this population.

2.1 Matrices in R

Now that you have found the matrix of this population, let us implement it in R. Set the initial population vector to the founder population (10 individuals in age class 1).

```
# Build the Leslie Matrix for the barn owl population

F1<- #insert your value here
F2<- #insert your value here
F3<- #insert your value here
F4<- #insert your value here

P1<- #insert your value here
P2<- #insert your value here
P3<- #insert your value here
P4<- #insert your value here

A<-matrix(c(F1,P1,0,0,F2,0,P2,0,F3,0,0,P3,F4,0,0,P4),
          nrow=4,byrow=FALSE)
A
# The initial population vector

n11<- #insert your value here
n12<- #insert your value here
n13<- #insert your value here
n14<- #insert your value here

n0<-c(n11, n12, n13, n14)
```

What happens if you set `byrow=TRUE` instead?

The next step is to project the population in the future. We have seen in the lecture that

$$\vec{n}(t+1) = \mathbf{A}\vec{n}(t) \quad (17)$$

To do so, we write the two following functions in R. The sign `%*%` is for matrix multiplication in R.

```
n1<-n0%*%A
nt2<-A%*%n0
```

Try to run both lines. One is incorrect, which one and why?

Next let us use this matrix to project the population. To do so we use a `for` loop over a specified time span. We first need to build an empty array with the `matrix` function where we store the data that we calculate during the loop. We call this array `n`, it is an array that has the same number of rows that the

matrix \mathbf{A} and has as many column as the time span we set. Thus each column corresponds to one year. \mathbf{n} will look like this:

$$\begin{pmatrix} N_{age=1,t=1} & N_{age=1,t=2} & N_{age=1,t=3} & \dots & N_{age=1,t=T} \\ N_{age=2,t=1} & N_{age=2,t=2} & N_{age=2,t=3} & \dots & N_{age=2,t=T} \\ N_{age=3,t=1} & N_{age=3,t=2} & N_{age=3,t=3} & \dots & N_{age=3,t=T} \\ N_{age=4,t=1} & N_{age=4,t=2} & N_{age=4,t=3} & \dots & N_{age=4,t=T} \end{pmatrix}$$

By first setting the time span to 4, check if we get the same population as the one described in the text. Then try different values of time span. To access column 5 of this matrix, you can type $\mathbf{n}[,5]$. Also in R the first index specifies the row number and the second one the column number. Because we want to see all rows at the same time, we leave out an index for the row. ($\mathbf{n}[3,5]$ would for example only give the entry for age class 3 at time 5.)

Complete the following code to calculate how the population develops over time

```
tspan <- ... #insert value for time span
rows <- ... # insert number of rows

# Build some matrices for storing eventual output
n <- matrix(0,nrow=rows,ncol=tspan)      # empty matrix

n[,1] <- c(...,...,...,...)              # insert value for the initial
                                         # population in each age class

# Project population forward and store output
for (t in ...){
  n[,t] <- .....      # %*% = matrix multiplication in R
}
```

The sum of each column is the total population size. We can then plot it.

```
Ntot<-colSums(n) # This calculates the sum
                # of all the age classes per time step
plot(Ntot, type="l", xlab="year", ylab="N(t)")
```

How does the population behave?

2.2 Asymptotic behaviour

Asymptotic rate of increase

From the matrix, we can find the asymptotic growth rate of that population. For this we need to look at the dominant eigenvalue of the population matrix. Remember from the lecture that the dominant eigenvalue of a population matrix

is the long term asymptotic rate of increase, λ . An eigenvalue of a matrix is a **scalar that when multiplied by a specific vector, gives the same result as when that vector is multiplied by the concerning matrix**. Mathematically this means:

$$\mathbf{A}\vec{v} = \lambda\vec{v} \quad (18)$$

the vector \vec{v} is not any vector but an eigenvector, that is a vector such that equation 18 holds. We will come back to it later. If you do not feel comfortable with the concept of eigenvectors/matrices, you might want to return to the last two exercises of the mathematical tools script.

In R we do not have to just see the eigenvectors, instead they can be found using the `eigen()` function.

```
eigens.A<-eigen(A)
eigens.A
```

Let us focus at the moment only on the first values. The first values returned by the function; 2.176, -0.463, -0.103, 0 are the eigenvalues of the matrix \mathbf{A} . A matrix has as many eigenvalues as it has dimensions. The only one we are interested in for now is the dominant eigenvalue, i.e. the largest eigenvalue. From looking at the eigenvalues, we can see that it is the first one. We thus extract the value in that position.

```
lambda2<-eigens.A$values[1]
```

We could have done this more directly:

```
lambda2<-eigen(A)$values[1]
```

What does this value of λ mean for the population on the long term?

Stable-age distribution

In the previous section, we looked at the growth of the whole population. It is also informative to examine what the population structure will look like on the long-term. We already calculated these numbers before, let us now plot them.

```
plot(log(n[1,]), type="l", col="blue", ylim=c(0,5),
      xlab="year", ylab="ln(n(t))")
lines(log(n[2,]), col="red")
lines(log(n[3,]), col="green")
lines(log(n[4,]), col="purple")
legend("topright",
      c("age class 1 ", "age class 2", "age class 3",
        "age class 4"),
      bty = "n",
```

```
lty=c(1,1,1,1),
col=c("blue", "red", "green", "purple"))
```

When reading the graph, keep in mind that the y -axis is logarithmic. We see that after five years, the age class trajectories are parallel to each other and growing with a constant rate. If a population is growing with constant birth and death rate, as is the case of our owl population, then the population converges to a stable age distribution. Once a population has reached the stable age distribution, it grows exponentially at the asymptotic finite rate. A population at the stable age distribution always has the same relative number of individuals in each age class every time step. However, the absolute number of individuals will change. The stationary age distribution is a special case of stable age distribution where the absolute number of individuals does neither increase nor decrease. The population is not growing. What is the asymptotic growth rate (λ) of such a stationary population?

The stable age distribution is given by the right eigenvector corresponding to the dominant eigenvalue. Let us now look at the vector elements of the **eigen**

function. The columns of `eigens.A$vector` are the right eigenvectors of the matrix **A**. When applying the matrix to them, it is the same as multiplying them by the corresponding eigenvalues, which are scalars. This means that the length but not the direction of this vector is changed by the matrix. Check this for the eigenvector corresponding to the dominant eigenvalue.

There are as many right eigenvectors as there are eigenvalues. To each eigenvalue one eigenvector corresponds. Its position is the same as the one of the dominant eigenvalue so we can extract it with the following lines of code.

```
w<-eigens.A$vector[,1]
w
```

The right eigenvector as such does not give us the proportion found in each age class. This is because the length of the vector is set to 1 instead of the sum of its elements (what is the difference between these two? Which is biologically more relevant? Which is mathematically more relevant?). However, to find the proportion of each age class, we want to rescale it (remember that if you find an eigenvector all vectors that point in the same direction are also eigenvectors. If we multiply an eigenvector by a scalar it thus remains an eigenvector.):

```
ssd <- w/sum(w)
ssd
```

Therefore we know now that a proportion of 0.68 of the population is in age class 1, 0.25 in age class 2, 0.06 in age class 3, and 0.01 in age class 4.

2.3 Sensitivity and elasticity analysis

Sensitivity analysis Sensitivities and elasticities of λ evaluate the relative importance of each matrix element for the asymptotic growth rate. Sensitivity is the effect of additive change in a matrix element on λ and the elasticity is the proportional effect of a proportional change in the parameter to λ .

The sensitivity tells us how an increase in absolute value of one of the parameters affects λ . How much does λ increase if the fertility of the age class 1 increases by a very small amount (for example 0.01)? Let us play around with the projection matrix and change each element of this matrix by 0.01 one by one to see how it affects λ .

```
# Build the Leslie Matrix for the barn owl population

F11<-      + 0.01 #insert your value here
F21<- #insert your value here
F31<- #insert your value here
F41<- #insert your value here

P11<- #insert your value here
```

```

P21<- #insert your value here
P31<- #insert your value here
P41<- #insert your value here

A1<-matrix(c(F11,P11,0,0,F21,0,P21,0,F31,0,0,P31,F41,0,0,P41), nr=4)
A1
lambdaF1<- lambda(A1)

```

The sensitivity of λ to one element of the matrix is given by:

$$s_{ij} = \frac{\partial \lambda}{\partial a_{ij}} = \lim_{\Delta a_{i,j} \rightarrow 0} \frac{\Delta \lambda}{\Delta a_{i,j}} \quad (19)$$

So the sensitivity can be approximated by taking the difference between the value of λ of the original matrix and the modified matrix and dividing it by the change we apply to the element of the matrix.

- $\partial \lambda$ can be approximated by the difference between the original λ and the new λ .
- ∂a_{ij} can be approximated by the difference between the original a_{ij} and the new a_{ij}

If the change to the element of the matrix is very small, the sensitivities calculated so will be close from the actual sensitivities. If you want to calculate all sensitivities using this approximation, it is probably best to use a **for** loop (or actually two, why two?). Do not forget to only change one matrix element at a time. Also investigate how small the change in the matrix element has to be to make sure that the approximation returns reasonable numbers.

* Exercise 3 Sensitivities

1. Calculate (by actually changing elements in the matrix one by one in R) the sensitivity of λ to each matrix element. *Hint: use two for loops in each other, in which you calculate for each element $A[i,j]$, how much λ would change if you would change that element a little bit.*
2. How much would the population rate change if you would increase the rate at location $[3,1]$ with a value of 0.1? Would you consider trying adapting this rate a good management strategy?

Elasticity analysis Elasticities are proportional sensitivities. Before we asked the question: if a matrix element increases by a small amount, how much does λ increase? Elasticities ask a different question: with what factor does λ change if a matrix element is changed by a certain factor. They thus examine the effect of a proportional change of transition elements on λ . For example, you may be interested in knowing by how much does λ change if the fertility of age class 2 is increased by 25%.

The elasticity of λ to a proportional change of one element of the matrix is given by:

$$e_{ij} = \frac{a_{ij}}{\lambda} \frac{\partial \lambda}{\partial a_{ij}} \quad (20)$$

* Exercise 4 Elasticities

1. Calculate the elasticities from the sensitivities that you found in the previous exercise
2. What is now the prediction for the effect of changing element [3,1]?

2.4 Transient dynamics

Most of what we have described above focuses on the asymptotic, (i.e. long-term) behaviour of the system. However, the short-term dynamics can be very different. In nature, a population may never be observed in the asymptotic regime. Transient dynamics focuses on short-term responses.

There are year-to-year variations in growth rate before the asymptote is reached. The code below calculate the annual finite growth rates of the barn owl population.

```
Ntot # the total population size vector.
      # Each element is the population size
      # at one time step. As calculated before
Ntott<-Ntot[2:(length(Ntot)+1)]
# the total population size at t+1

R<-Ntott/Ntot
# the annual finite growth rates
#vector
```

We can plot this in a graph to see how much time it takes this population to reach the asymptotic finite growth rate. For this we first create a vector of the same length as the annual growth rate vector in which all elements contain the value of λ .

```
lam<-lambda(A)

plot(R, type="l", col="blue", xlab="year", ylab="growth rate")
abline(h=lam, col="red")
legend("topright",
      c("annual growth rate","asymptotic growth rate"),
      bty = "n",
      lty=c(1,1),
      col=c("blue", "red"))
```

How long does it take before the population reaches its asymptotic growth rate?

3 Stage structured matrices

Everything that we have discussed for age based matrices so far also holds for stage structured populations. The main difference between the two is that an age based matrix only know two types of transitions: due to survival, individuals in age class a can only get into age class $a + 1$ at the next time step. The only other possible contribution is due to reproduction, which allows a contribution from age class a to the first age class. It is impossible however, for individuals from age class a to end up in age class $a + 2$ after one time step (you can not get two years older in one year of time!). It is also not possible to stay in the same age class! Hence, a lot of transition rates are 0 in such matrices.

When we instead classify a population in stages rather than ages, we do not have this property anymore. Say we have three stages: small individuals, medium-sized individuals and big individuals. Due to extreme growth, a small individual might become a big individual after one time step, or maybe it doesn't grow at all and it might stay small. Furthermore maybe a big individual may, after a harsh winter with almost no food, become a medium-size individual. Hence, much less matrix elements will be zero.

In the following exercise we are going to look at a stage structured population. Here, we only look at a 2×2 matrix, but for larger matrices the same procedure can be followed, leading to the same conclusions about the dominant eigenvector and the stable stage distribution.

3.1 Eigenvector decomposition

**** Exercise 5 Eigenvector decomposition**

1. We consider a population that consists of only two classes: juveniles and adults. After one time step, 60% of the juveniles stay juveniles, 20% become adults and the remaining 20% dies. The adults have a 80% chance of survival and produce 0.5 juveniles on average. We thus have the following matrix:

$$\mathbf{A} = \begin{pmatrix} 0.6 & 0.5 \\ 0.2 & 0.8 \end{pmatrix} \quad (21)$$

Now consider the following population:

$$\vec{n}(0) = \begin{pmatrix} 5 \\ 2 \end{pmatrix} \quad (22)$$

- a) Calculate $\vec{n}(1)$ up to $\vec{n}(4)$.

We are now going to try and find a more direct way to find $\vec{n}(t)$. For this, we realize that we can write $\vec{n}(0)$ as a combination of the two eigenvectors:

$$\vec{n}(0) = c_1 \vec{v}_1 + c_2 \vec{v}_2 \quad (23)$$

We can now obtain the eigenvalues and eigenvectors of this matrix:

$$\lambda_1 = 1.03, \lambda_2 = 0.37 \quad (24)$$

$$\vec{v}_1 = \begin{pmatrix} 0.76 \\ 0.65 \end{pmatrix}, \vec{v}_2 = \begin{pmatrix} 0.91 \\ -0.42 \end{pmatrix} \quad (25)$$

- b) Calculate c_1 and c_2 . Now we use this notation, to find an expression for $\vec{n}(t)$. Let us first find a notation for $\vec{n}(1)$:

$$\vec{n}(1) = \mathbf{A}\vec{n}(0) = \mathbf{A}(c_1 \vec{v}_1 + c_2 \vec{v}_2) = c_1 \mathbf{A}\vec{v}_1 + c_2 \mathbf{A}\vec{v}_2 \quad (26)$$

- c) Use the properties of eigenvectors to rewrite the right side of the above equation into a form that does not contain \mathbf{A} anymore, and instead contains λ .
d) Using the same notation, what is the value of $\vec{n}(2)$?
e) And $\vec{n}(t)$? Verify this answer by calculating $\vec{n}(1)$ up to $\vec{n}(4)$ using the equation you found.
f) If $t \rightarrow \infty$, a stable stage distribution is reached. What does this distribution look like? How can you see that from your answer to the previous question?
g) How much does the population grow at this point? Is this a stable population?

3.2 Reproductive values

The reproductive value vector represents the contribution of each individual to present and future reproduction. In other words, it gives how much an individual in a given age class contributes to the population on the long-term, including offspring of its offspring. That is: if we have a population and its matrix at time $t = 1$, what proportion of individuals at a much later time will be descendants of individuals in age class 1 at time $t = 1$ and how many from individuals in age class 2 etc. Mathematically, the reproductive value vector is the left eigenvector of the population matrix.

$$\vec{v}A = \lambda \vec{v} \quad (27)$$

Please note that this time the vector is on the left side instead of on the right side of the matrix. This is why this is called a left eigenvector. Multiplication with the vector on the left side of the matrix looks as follows in 2 dimensions:

$$\begin{pmatrix} v_1 & v_2 \end{pmatrix} \begin{pmatrix} a_{1,1} & a_{1,2} \\ a_{2,1} & a_{2,2} \end{pmatrix} = \begin{pmatrix} v_1 a_{1,1} + v_2 a_{2,1} & v_1 a_{1,2} + v_2 a_{2,2} \end{pmatrix} \quad (28)$$

Again, we take the row from the first element (in this case the vector) and multiply its elements by the elements of the first column of the second element

(in these case a matrix). Adding up these contributions gives us the value for the first entry of the final vector. Compare this to what you would get if the order of the matrix and the vector would be the other way around.

To get the left eigenvector of a matrix, we need to perform the eigen analysis on the transpose of the projection matrix. (The transpose of a matrix is the matrix we get by exchanging the rows and the columns of that matrix. For example for the matrix $\mathbf{B} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$, \mathbf{B}^T is the transpose of matrix \mathbf{B} and $\mathbf{B}^T = \begin{pmatrix} a & c \\ b & d \end{pmatrix}$). More visually: when you transpose a matrix, you mirror its elements in the diagonal of that matrix. `t()` is the R function that transposes a matrix. If you do not remember what the function `eigen` does, reread the subsection *asymptotic rate of increase* or aks R (`?eigen`).

```
At<-t(A)
eigens.At<-eigen(At)
eigens.At
```

We apply the same procedure as for the right eigenvector to find the left eigenvector and the eigenvalue. Write the code to extract the eigenvalue and the left eigenvector. Do you notice anything about the eigenvalue? Check that the found dominant left eigenvector is indeed a left eigenvector of the matrix with the dominant eigenvalue as its eigenvalue.

Additional information: Reproductive values more in depth

If you want to understand the interpretation of the reproductive values more closely, take a look at the following (not too elegant) code:

```
B<-matrix(4*runif(9),nrow=3) # We generate a random matrix

B

##           [,1]      [,2]      [,3]
## [1,] 2.1968375 2.0173937 3.283666
## [2,] 0.6736884 0.4535915 1.412944
## [3,] 2.9945209 3.7267266 1.437080
```

We output B, in case you want to repeat the simulation yourself

```
eigen(t(B))$vectors[,1]/sum(eigen(t(B))$vectors[,1])

## [1] 0.3226698 0.3414054 0.3359247

# We calculate the dominant left eigenvector of this matrix
# and normalise it with respect to the sum of its elements
```

Now we want to investigate what would happen to the following 3 initial populations:

- (1,0,0)
- (0,1,0)
- (0,0,1)

```
N1<-rep(NA,3)
# Create an empty vector for storing the final population
# size if we start with any of the three initial populations
for(i in 1:3){
  N<-rep(0,3)
  N[i]<-1
  # Set the initial population vector
  # the first time it will be (1,0,0)
  # then (0,1,0) and finally (0,0,1)

  for(t in 1:40){
    # we project the population for 40 timesteps
    N<-B%*%N
  }
  N1[i]<-sum(N)
  # We store the total population size after 40 timesteps
  # in the vector N1
}
N1/sum(N1)

## [1] 0.3226698 0.3414054 0.3359247

# We output the normalised version of N1, which should be
# equal to the left eigenvector, do check this!
```

You can interpret this as follows: if we for example start with a population $\begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix}$, after 40 years, 32% of the total population will have originated from

the individual that was initially in age class 1, 34% from the individual in age class 2 and the remaining 34% of the total population at timestep 40 from the individual that was in age class 3 in the initial population. *Please note that since we took completely random numbers to construct the matrix, the matrix is unlikely to have biological relevance. But the concept of course remains the same for more relevant matrices.*

However, what would happen if the initial population would look as follows:

$\begin{pmatrix} 2 \\ 1 \\ 1 \end{pmatrix}$? If we project this initial population in the future we find (the code is omitted this time):

```
## [1] 0.4879069 0.2581184 0.2539747
```

This means that after 40 years, 49% of the total population will have originated from the two individuals that were initially in age class 1, 26% from the individual in age class 2 and the remaining 25% of the total population at timestep 40 from the individual that was in age class 3 in the initial population. These numbers do not correspond to the left eigenvector, yet they do relate to the left eigenvalue. First we need to realize that if 49% of the final population originated from the two individuals in age class 1 in the initial population, this means that each of these two individuals is responsible for 24.5% of the final population. It is of course fairer to compare these numbers with each other (so after correcting for the number of individuals that we started with):

$$\begin{pmatrix} 24.5 \\ 26 \\ 25 \end{pmatrix}$$

However, now the numbers no longer add up to 100%. Since all we care about is the ratio between the different contributions, we can just divide all of them by the sum of the three contributions ($\approx 24.5 + 26 + 25$) and multiply the total by 100 (just to make sure that all the percentages add up to 100). What we get now is:

$$\begin{pmatrix} 32.27 \\ 34.14 \\ 33.59 \end{pmatrix}$$

This is indeed again the left eigenvector! (Hopefully. Every time we save this document new random numbers are generated, so actually we can only hope that the theory is general enough to work for all random matrices B that are accidentally generated...). We see thus that the left eigenvector actually mainly tell you how many more offspring an individual that starts

in a certain age class will have compared to individuals in other age classes on the long term. – This is indeed a relatively difficult concept, but maybe if you think about it and go over this simulation yourself, it might sink in.
